Poisson's ratio and modern materials

G. N. Greaves, A. L. Greer, R. S. Lakes and T. Rouxel

In comparing a material’s resistance to distort under mechanical load rather than to alter in volume, Poisson’s ratio offers the fundamental metric by which to compare the performance of any material when strained elastically. The numerical limits are set by $\frac{1}{2}$ and $-1$, between which all stable isotropic materials are found. With new experiments, computational methods and routes to materials synthesis, we assess what Poisson’s ratio means in the contemporary understanding of the mechanical characteristics of modern materials. Central to these recent advances, we emphasize the significance of relationships outside the elastic limit between Poisson’s ratio and densification, connectivity, ductility and the toughness of solids; and their association with the dynamic properties of the liquids from which they were condensed and into which they melt.

Whereas different materials respond to stress by hugely different amounts, Poisson’s ratio, $\nu$, is contained within narrow numerical bounds, embracing the mechanical properties of every isotropic material, from the most incompressible to the most extendable, from the softest solid to the strongest liquid. Convolving mechanical response at the atomic level with the intervening linkages to the macroscopic scale, Poisson’s ratio provides a universal way to contrast the structural performance of real materials, whether homogeneous or not. Taking this wide perspective, we show how Poisson’s ratio has provided inspiration for creating new solids and liquids, and challenges in understanding existing ones. Concentrating on glasses, ceramics, polymers and metals, we review the progress made in understanding modern materials and generating new ones such as those with negative Poisson’s ratios. The influence of packing and connectivity is emphasized, together with overarching relationships recently discovered between Poisson’s ratio and relaxation in supercooled antecedents, and also between fracture and elasticity in the solid state. In the 200th year since the publication of Poisson’s Traité de Mécanique (Box 1), this is a good time to take stock of the utility of Poisson’s ratio.

Definition and physical significance

Poisson’s ratio $\nu$ defined the ratio $\nu$ between transverse strain ($\epsilon_t$) and longitudinal strain ($\epsilon_l$) in the elastic loading direction as $\nu = -\epsilon_t/\epsilon_l$ (Box 1). Once it was recognized that elastic moduli are independent, it could be seen that the two most appropriate for formulating $\nu$ are the isothermal bulk modulus, $B = -\frac{dP}{dV}$, where $x$ is the isothermal compressibility, and the shear modulus $G = \sigma/2\epsilon_t$ (ref. 6), as these are representative of the change in size and shape respectively. For isotropic materials, $\nu$ must satisfy $-1 \leq \nu \leq \frac{1}{2}$ (Box 2). This numerical window is illustrated in Fig. 1a where $\nu$ is plotted as a function of $B/G$ for a host of materials. Starting with compact, weakly compressible materials such as liquids and rubbers, where stress primarily results in shape change, $\nu \searrow \frac{1}{2}$. For most well-known solids such as metals, polymers and ceramics, $0.25 \leq \nu \leq 0.35$. Glasses and minerals are more compressible, and for these $\nu \to 0$. For gases, $\nu = 0$, and network structures can exhibit $\nu < 0$ (ref. 7). Materials with negative Poisson’s ratio are called ‘auxetic’. Re-entrant foams were the first reported (Fig. 2a) but subsequently it was shown that auxeticity is a common feature of a variety of honeycomb structures and networks (Fig. 2b–d), where $\nu$ can take both positive and negative values, depending on orientation, with aggregate values that can be negative. Critical fluids are the most highly compressible materials for which $\nu \to -1$. The huge diversity of elastic properties of modern and natural materials can also be viewed in plots of $B$ versus $G$ (ref. 11), as shown in Fig. 1b. This is also helpful in distinguishing ductile from brittle behaviour beyond the elastic limit (Fig. 1c).

Nonlinear regime

The concept of Poisson’s ratio can be extended into the nonlinear regime, to describe elastomers such as rubbers as well as glass fibres, when subjected to gigapascal tensile stresses. Spectacular changes of $\nu$ also occur in anisotropic auxetic materials outside the isotropic range of $-1 \leq \nu \leq \frac{1}{2}$ at small strains. For instance, $\nu$ was found to decrease from 0 to $-14$ for an anisotropic expanded PTFE in a true strain range of 0.03 (ref. 17). In viscoelastic media (foodstuffs such as starch and thermoplastics such as poly(methyl methacrylate), PMMA), the mechanical response is non instantaneous or isochronal (Fig. 2e). Instead $-\epsilon_t/\epsilon_l$ defines an apparent $\nu$ regardless of the constitutive law that defines whether it is elastic or not. In particular, $\nu^*(t)$ is a complex function of frequency $f$ or a function $\nu(t)$ of time $t$ which can be obtained from creep and stress relaxation functions (refs 18, 19). Volume and shape change processes can have different kinetics, and deformation is usually the combination of elasticity, delayed elasticity and various inelastic processes. Despite these complexities an increase of $\nu(t)$ with time is often reported, Poisson’s ratio tending to $\frac{1}{2}$ for most polymer materials. This can be viewed as a shift from elasticity (accompanied by volume change) to viscoelastic or even viscoplastic flow (almost volume conservative) as time passes (Fig. 2e). Conversely, $\nu^*(t)$ decreases with increasing frequency because the elastic regime is favoured at high rates.

Physical significance

Materials with different Poisson’s ratios behave very differently mechanically. Properties range from ‘rubbery’ to ‘dilatational’, between which are ‘stiff’ materials like metals and minerals, ‘compliant’ materials like polymers and ‘spongy’ materials like foams. The physical significance of $\nu$ is revealed by various interrelations between theoretical elastic properties. These are illustrated in the Milton map of bulk isothermal modulus $B$ versus shear modulus $G$ (Fig. 1b, 12, 13). When $B/G \gg 1$ and $\nu \to \frac{1}{2}$ in Fig. 1b (vertical axis), materials are extremely incompressible, like rubber,
Poisson’s ratio is intimately related to the speed of sound, in terms of the transverse (shear) and longitudinal (compressive) $V_B$ and $V_L$ velocities, respectively. The ratio $\nu = 1 - \frac{V_T^2}{2V_L^2} = \frac{V_L^2 - V_T^2}{V_L^2}$. For isotropic materials, it holds that $\nu = \frac{V_T}{V_L}$. The Poisson ratio relates to the fractional change in the transverse dimension to a change in the longitudinal dimension. It is typically negative for most solids and zero for fluids, indicating that solids tend to contract in the transverse direction when stretched longitudinally.

### Box 1 | Historical perspective.

Siméon Denis Poisson (1787–1840) was born in the village of Pithiviers (Loiret, France). A brilliant scholar, especially talented in mathematics, he excelled in the entrance exam for the prestigious École Polytechnique in Paris. He then devoted his life to the exploration of various fields of mathematical physics, and to solving many problems of great practical importance. Poisson’s name survives in Poisson’s integral, Poisson’s distribution in statistics, Poisson’s constant in electricity, and Poisson’s ratio. In 1811 Poisson published the *Traité de Mécanique*, pictured here, which remains a classical handbook in mechanics. It came in two volumes and can be found in national libraries worldwide as well as on the Internet.

An analysis of the shape and volume changes of a fluid under arbitrary loading is introduced in the second volume. However, it was only in 1827 that Poisson, starting from an explicit molecular interaction hypothesis formulated several years earlier by the French engineer and physicist Navier, proposed an expression (see right-hand image) for the change in cross-sectional area ($8S/S = -\beta$) stemming from the elongation ($6L/L = \epsilon$) of an elastic wire and suggested that $\beta = c/2$. As $\beta = 2\epsilon/\nu$, so $\nu = 1/4$. Poisson considered this result as being in perfect agreement with nature based on an experiment conducted on a brass rod ($\nu \approx 0.357$) by his contemporary Cagniard de Latour. But it became clear, first through Cauchy in his *Exercices de Mathématiques* and later especially after the experiments performed by Voigt, that two independent moduli of elasticity are necessary to characterize the elastic behaviour of isotropic materials. Accordingly $\nu$ must differ from one material to another, even crystalline materials in the same class.

**Notre sur l’Extension des Fils et des Plaques Elastiques.**

*Par M. Poisson.*

Sor la longueur d’un fil élastique qui ait porté la même épaisseur; soit $\beta$ l’aire de la section normale à sa longueur, et par conséquent $a\beta$ son volume. Supposons qu’on lui fasse subir une petite extension, je sors que sa longueur deviendra $a \left(1 + \frac{\beta}{a\beta} \right)$, égale à une très petite fraction; en même temps le fil s’amincira, et si nous disposons par $b \left(1 + \epsilon \right)$ ce que deviendra l’aire de la section ordinaire, $\epsilon$ étant aussi une très petite fraction, son nouveau volume sera à très peu près $ab \left(1 + \epsilon \right)$. Or, d’après la théorie des corps élastiques que j’exposerai dans un prochain Mémoire, on doit avoir:

$$\epsilon = \frac{1}{2}$$

D’où il résulte que par l’extension d’un fil élastique, son volume se trouve augmenté, suivant le rapport de $1 + \epsilon$ à l’unité, et sa densité diminuée suivant le rapport inverse.

Ce résultat s’accorde parfaitement avec une expérience que M. Cagniard-de-l’Hauvres a communiquée récemment à l’Académie, et dont voici la description.

**Notes on the Extension of Rods and Plates.**

*By M. Poisson.*

When a long rod of an elastic material is elongated, its cross-sectional area changes, and the volume increases by a factor of $1 + \epsilon$. This simple expression indicates how the volume of an elastic body changes under deformation, providing a fundamental concept in the study of elasticity.

---

**Box 2 | Packing densities.**

Most liquids and also granular solids. When $B/G << 1$ and $\nu \rightarrow -1$ in Fig. 1b (horizontal axis), materials are extremely compressible, examples being re-entrant foams and molecular structures. Common materials fall between these extremes. Materials possessing stiff arms or struts in directions normal to the loading axis such as honeycomb structures loaded along the $c$ axis, will resist transverse contraction and exhibit $\nu = 0$ as cork does (Fig. 2d) or $\nu < 0$ as some zeolites might (Fig. 2b). For ceramics, glasses and semiconductors, $B/G = 5/3$ and $\nu \rightarrow 1/4$ (refs 26–29). Likewise, metals are stiff and have Poisson’s ratio $\nu \rightarrow 1/2$. Crystalline metals are less densely packed, typified by hard metals like steel for which $\nu \approx 1/3$. By contrast, the density of covalent solids is less and so is Poisson’s ratio. Finally, auxetic materials have dilational re-entrant architecture and $\nu < 0$.

This correlation between $\nu$ and atomic packing density $C$, has only recently been recognized (Fig. 3) because it is rather difficult to define in complex solids. Concomitant effects, like temperature and pressure, also sometimes obscure the underlying structural effect. The case of pure crystalline substances seems particularly complicated. At first sight Poisson’s ratio tends to increase with the atomic packing density so that $\nu_{\text{cd}} < \nu_{\text{bcc}} < \nu_{\text{fccc}}$ (where cd, bcc, fcc
Box 2 | Poisson’s ratio, Angell plot, non-ergodicity and terahertz vibrations.

Defining Poisson’s ratio

Poisson’s ratio \( \nu \) compares the strains in the transverse \( \epsilon_t \) and longitudinal \( \epsilon_L \) directions under uniaxial stress: \[ \nu = -\epsilon_t/\epsilon_L = -(\Delta D/D)/ (\Delta L/L) \] (panel a). For isotropic materials, \( \nu \) can be expressed in terms of the bulk modulus \( B \) and the shear modulus \( G \), which relate to the change in size and shape respectively: \[ \nu = \frac{3(B/G - 2) + 6(B/G + 2)}{12} \] (ref. 26). This defines numerical limits for Poisson’s ratio, \( -1 \leq \nu \leq \frac{1}{2} \) for \( 0 \leq B/G < \infty \). Poisson’s ratio can also be written in terms of the longitudinal and transverse speeds of sound, \( V_L \) and \( V_T \), respectively: \[ \nu = \frac{\frac{1}{2}(V_T^2 - 1)}{(V_L/V_T)^2 - 1} \]. Alternatively, \( \nu = \frac{3 - (V_T/V_L)^2}{3 + (V_T/V_L)^2} \) where \( V_g = \sqrt{B/\rho} \), the so-called bulk speed, which is directly measured in liquids, where \( \nu = \frac{1}{2} \) and \( V_T = 0 \). For examples and demonstrations, see http://silver.neep.wisc.edu/~lakes/Poisson.html.

Melt fragility

Panel b shows an Angell plot, \( \log \eta \) versus \( T/T_g \), of glass-forming liquids \((\eta) \) where \( \eta \) is the shear viscosity and \( T_g \) the glass transition. The glass transition is defined by \( \eta(T_g) = 10^{12} \) Pa for all glass-forming liquids. From the Maxwell viscosity relation \((\eta = G_\infty \tau)\) the Angell plot can also be expressed as a function of structural relaxation time \( \tau \): \( \log \tau \) versus \( T/T_g \). Because for many supercooled materials the instantaneous shear modulus \( G_\infty \) lies in the range 10 to 30 GPa, the glass transition can also be defined by \( \sigma(T_g) \approx 100 \) s. The melt fragility is defined by \( m = (\partial \log \eta/\partial (T/T_g))_{\tau=\tau_0} \) which distinguishes strong liquids like silica \( (m \approx 20) \) from fragile liquids like PMMA \( (m \approx 118) \) at \( T_g \). At the melting temperature \( T_m \), which is typically related to the glass transition \( T_g \) by \( T_m/T_g \approx 3/2 \), the viscosities of strong and fragile liquids can differ by many orders of magnitude, directly affecting the viscoelastic timescale of melting. Examples of \( m \) changing from strong to fragile liquids with compression are shown in Fig. 8c and d.

Non-ergodicity in supercooled liquids and glasses

The non-ergodicity factor \( f_0 \) versus \( T/T_g \) which is measured in Brillouin and inelastic X-ray scattering \((\eta) \), records the departure from thermodynamic equilibrium and increases from the supercooled liquid to the glass as the temperature falls (panel c; CKN is K‘Ca\(^{3+}\)NO\(_3\)). In particular, \( f_0 = (1 - a T/T_g)^{-1} \), where \( a \) is a constant \((0.001 \text{ to } 1) \). The factor \( f_0 \) is a measure of the magnitude of density fluctuations present at a given temperature and to a first approximation \( f_0 \approx (V_g/V_L)^2 = 3G/(4G + 3B) \). It follows that \( a \propto B/G \), in which case \( a \) scales with Poisson’s ratio as both scale with \( m \). Figure 7b illustrates empirically \( m \) versus \( a \) for a variety of organic and molecular glass-forming liquids with a wide range of fragilities.

Terahertz vibrations and the boson peak

Terahertz vibrations, measured directly by inelastic neutron scattering, are typified by librational modes that characterize the dynamics of tetrahedral glasses and microporous crystals \((\eta) \), as illustrated in panel d. These dynamics are embraced by the boson peak \((\eta) \) illustrated in Fig. 8a and b. For glasses in general, the intensity of the boson peak \( A_{BP} \) is governed by the statistical fluctuations in density, which are related in turn to the elastic moduli \((\eta) \). Accordingly, from panel a, the size of the Boson peak at a given temperature is reciprocally related to Poisson’s ratio and empirically to the parameter \( a \) from panel c, which is inversely related to the non-ergodicity factor \( f_0 \). From Fig. 7a and b, \( A_{BP} \) must also be inversely related to the melt fragility \( m \), which (from panel b) can differ by orders of magnitude, from the strongest to the most fragile glass-forming liquids. Furthermore, from Fig. 1c and 7c, \( A_{BP} \) for a glass decreases as the fracture energy increases, distinguishing brittle from ductile materials. Glasses obtained from strong liquids are the most brittle and have the largest boson peaks. Conversely, boson peaks are smallest in glasses quenched from fragile liquids. Broadly speaking, terahertz vibrations drive the dynamics of glass formation and phase transformations \((\eta) \) (Fig. 5)—including melting. Figure adapted with permission from: panel b, ref. 107, © 2001 NPG; panel c, ref. 79, © 2007 Taylor & Francis.
Considering polycrystalline solids, these are macroscopically isotropic and have Poisson’s ratios of \( \nu_c(0.2) < \nu_c(0.22) < \nu_c(0.278) \) for tetravalent elements, and for the hcp polymorphs of \( \nu_c(0.25) < \nu_c(0.3) \) or \( \nu_c(0.32) < \nu_c(0.36) < \nu_c(0.37) \), just to mention a few. Lead (\( \nu_{\text{Pb}} = 0.44 \)) and thallium (\( \nu_{\text{Tl}} = 0.45 \)) with high \( Z \) have remarkably high Poisson’s ratios. In the case of crystalline structures, the valence electron density plays a key role, and \textit{ab-initio} calculation is becoming an increasingly popular approach following the early work of Cohen\(^{27}\). Subsequently, the cases of diamond semiconductors (\( \nu_{\text{Si}} = 0.22 \) and \( \nu_{\text{Ge}} = 0.28 \)) were reported\(^{28}\), as were the fullerites\(^{29}\), molybdenum\(^{30}\) and most recently dental amalgams\(^{31}\). There are, however, isolated cases where the interpretation is not straightforward. Most data are measured under ambient conditions, whereas \( \nu \) is known to generally increase with temperature (see Fig. 4b). High melting points thus favour low Poisson’s ratio (everything else remaining unchanged) and vice versa. This is possibly why tungsten, being more refractory than molybdenum, has a smaller Poisson’s ratio and why beryllium, combining low \( Z \) with a comparatively high melting point (1,560 K), exhibits a remarkably small Poisson’s ratio of 0.032 and is also very brittle.

Paradoxically, complex materials such as polycrystalline glasses follow simple monotonic trends. In this case the atomic packing density \( C_v \) is defined as the ratio between the minimum theoretical volume occupied by the ions and the corresponding effective volume of the glass (Fig. 3). For instance, \( C_v \) is about 0.52 for a standard window glass and 0.45 for silica glass. An estimation of the packing density in metallic glasses can be obtained using the atomic packing density in metallic glasses can be obtained using the atomic volume of the glass (Fig. 3). Eventually, within limited compositional ranges, linear trends can be observed\(^{42}\). Much earlier, Makishima had proposed that \( \nu = \frac{1}{2} - \frac{1}{2}C_v \) for silicate glasses\(^{43}\) but without knowledge of accurate atomic glass network parameters, such as interatomic distance and coordination number.

Nevertheless, a direct comparison of Poisson’s ratio for specimens of identical composition and initial structure but submitted

Time-dependent Poisson’s ratio for poly(methyl methacrylate), PMMA, showing the gradual rise in $\nu(t)$ with relaxation under uniaxial shear from the instantaneous elastic value of 0.33 to the viscoelastic and eventual incompressible bulk value of 0.5. Figure reproduced with permission from ref. 20, © 1997 Wiley.

Materials with small Poisson’s ratio are more easily compressed than sheared (small $B/G$), whereas those with High Poisson’s ratio resist compression in favour of shear (large $B/G$). The ability of a material to dissipate the elastic loading energy by any permanent deformation mechanism ultimately governs its cracking resistance. Indeed the brittle–ductile transition in terms of $\nu$ is striking—particularly in metals (Fig. 7c).

Connectivity and temperature High packing density is incompatible with structures that are highly connected; consider the random packing of balls (6D) versus rods (1D) or polyhedral frames (2D and 3D) in a box. Judging from the correlation with $C_v$ (Fig. 3), $\nu$ is expected to decrease with increasing connectivity (Fig. 4a), not least because stiff arms in cross-linked structures oppose transverse contraction upon tensile loading. The relatively low values of $B/G$ and hence $\nu$ for diamond, fullerite and hard materials in general (Fig. 3) is an indication of the high degree of directional covalent bonding. In the case of glasses, the degree of cross-linking of the atomic network built on glass-forming elements can be used as a first approach, in lieu of an accurate description based on the electron band structure.

For glasses with covalently bonded atoms the mean coordination number $<n>$ is a useful index of the connectivity (Fig. 4a). For
example, for a Ge\textsubscript{1−x}Se\textsubscript{x} (x < 1) glass, <n> = 2(x + 1). Provided <n> is less than 2.1, the volume fraction of Ge-containing chains is negligible so that deformation essentially proceeds through the alignment of chains, with elastic properties expected to be dominated by weak inter-chain van der Waals forces, analogous to polymeric materials. Accordingly shear resistance is small and v large. As <n> increases, covalent bonds come into play and a three-dimensional network builds up, leading to a significant decrease in v. For oxide glasses, the number of bridging oxygen atoms, n\textsubscript{BO} per glass-forming cation (Si, Al, Zr, As, B, P and so on) provides a straightforward estimation of network crosslinking, where BO refers to bridging oxygens.

The material composition, however, is insufficient to interpret the observed correlation between v and the connectivity. Temperature comes into play. This is because elastic properties are very sensitive to temperature and v is expected to increase in crystalline materials as the melting point (T\textsubscript{m}) is approached or in glasses above the glass transition temperature (T\textsubscript{g}) (Fig. 4b and 5c). A steep increase in Poisson’s ratio reveals rapid network depolymerization, as is the case for organic chain polymers such as glycerol or polystyrene and also for a-B\textsubscript{2}O\textsubscript{3} (ref. 42) which transform into fragile liquids (Box 2). In cellular materials, such as open-cell foams, the reduction of the volume fraction of solid (\(\phi\)) weakens the interconnections favouring bending with respect to axial deformation, analogous to an increase of temperature in dense solids. Indeed the analysis of foam structures\textsuperscript{49} predicts that \(\nu\) increases as \(\phi\) decreases. For glasses like silicates and aluminosilicates forming strong liquids above T\textsubscript{g} (Box 2), v increases far more slowly (Fig. 4b).

In the face of this complexity, we note that glasses offer a unique opportunity to tune the composition smoothly to change the packing density and/or the connectivity. One can hence produce glasses with Poisson’s ratio à la carte.

**Auxetic materials** The theory of elasticity allows values of Poisson’s ratio for isotropic solids down to −1 (Fig. 1a). Although for years the possibility of negative v was excluded\textsuperscript{61}, re-entrant foams (Fig. 2a) achieved values as negative as −0.8 (refs 9–13). Fabricated under pressure, they are isotropic if compression is triaxial or anisotropic under extrusion conditions. They have been called ‘anti-rubber’ because they are opposite in elastic response to rubber (Fig. 1b). The effect in foam or honeycomb occurs by the unfolding of re-entrant cells as they are stretched (Fig. 2a). By contrast in typical foams, the cells are convex so their deformation gives rise to a ‘normal’ positive Poisson’s ratio. A coarse cell structure is not required to predict a positive or negative Poisson’s ratio; classical elastic properties have no length scale\textsuperscript{62}. Rigid mechanical models, such as rotating hinged squares and triangles, replicate auxetic behaviour and serve as models for molecular structures and designs (Fig. 2b)\textsuperscript{7,8,25,63,64}. It is not necessary to have empty space in a microstructure to achieve the effect: hierarchical two-phase laminates with a chevron structure and transforms into high-density amorphous (HDA) ice\textsuperscript{59}. This differs from LDA ice by the presence of interstitial molecules\textsuperscript{64} that interrupt the network topology.

For pure oxide glasses such as As\textsubscript{2}O\textsubscript{3}, B\textsubscript{2}O\textsubscript{3} and P\textsubscript{2}O\textsubscript{5}, n\textsubscript{BO} = 3 and v = 0.3, whereas for a-SiO\textsubscript{2} and a-GeO\textsubscript{2}, n\textsubscript{BO} = 4 and v = 0.2. Nuclear magnetic resonance measurements show mostly to experimental n\textsubscript{BO} values that are very close to the theoretical ones. It should be emphasized, though, that <n> and n\textsubscript{BO} are not equivalent. For instance, in the case of a-SiO\textsubscript{2}, <n> = 2.67 whereas n\textsubscript{BO} = 4. Highly crosslinked networks, such as silica glass, lead to small Poisson’s ratios (0.19), whereas weakly correlated networks, such as chain-based chalcogenide glasses or cluster-based metallic glasses, show values between 0.3 and 0.4 (Fig. 4a)\textsuperscript{42}. Hence, as already noticed by Bridge and Higazy\textsuperscript{41} in a study limited to some oxide glasses, and by Sreram et al.\textsuperscript{86} for chalcogenide glasses and later generalized by Rouxel\textsuperscript{67} for a wide range of glasses including covalent and metallic ones, v depends almost linearly on connectivity and increases as the dimensionality of the structural units decreases.

## Figure 3 | Poisson’s ratio and atomic packing.

Poisson’s ratio \(\nu\) as a function of the atomic packing density \(C_5 = \rho\Sigma f_i/\Sigma M_i\), where \(\rho\) is the specific mass, N is Avogadro’s number, \(r_i\) and \(r_s\) are the ionic radii, \(f_i\) is the molar fraction and \(M_i\) is the molar mass. For the ith constituent with chemical formula A\textsubscript{B}_\textsubscript{x} V\textsubscript{y} = (4/3) πN(2r_i^\text{ion} + yr_s^\text{ion})^3. The distinct symbols show that there are monotonic and nearly linear increases of \(\nu\) with \(C_5\) for each separate chemical system\textsuperscript{42}. Figure adapted with permission from ref. 42, © 2007 Wiley.
multiple length scales can approach the isotropic lower limit $\nu = -1$ (ref. 11). These microstructures are played out in the α-cristobalite network (Fig. 2c). Microstructures such as composites with rotating discs and units, magnetic films, hypothetical granular structures or plasmas in neutron stars can also exhibit such effects\(^{(2,3,42)}\).

Negative Poisson's ratio can result in enhanced toughness. The mode I (opening) fracture stress of a structure from a pre-existing flaw is proportional to $\sqrt{\gamma E/a(1 - \nu^2)}$, where $\gamma$ is the fracture surface energy, $E$ is Young's modulus, and $a$ is the critical flaw size. For Poisson's ratio approaching $-1$, the material is expected to become very tough. Likewise it should resist indentation as the contact surface area is proportional to $(1 - \nu^2)/E$. Even if the material is compliant, provided $\nu$ is close to the thermodynamic limit of $-1$ (Fig. 1b), it will be difficult to indent. Other anticipated enhancements include improved shear stiffness, self-adaptive vibrational damping and shock absorption, with applications in body armour, increased-sensitivity piezoelectric composites, fibre composites with greater pull-out resistance, a natural tendency to form dome-shaped surfaces (synclastic curvature), foams with improved filter performance and drug release, more comfortable textiles with reduced clothing pressure and so on\(^{(8,23,44)}\).

**Anisotropic behaviour** Anisotropic materials, including crystals and fibrous composites, have directional elastic properties where $\nu$ depends on orientation. For example, the Young's modulus and Poisson's ratio of a crystal can change significantly with direction. In composites, the anisotropy can arise from the orientation of the fibres, the alignment of the matrix, or the texture of the parts being bonded.

**Figure 4 | Connectivity in glasses and liquids.** Poisson's ratio $\nu$ in glasses and liquids reflects their structure and its dependence on temperature. a, In glasses $\nu$ varies with the average coordination number $<n>$ in chalcogenide glasses, or the number of bridging oxygens per glass-forming cation $n_\text{BO}$ in oxide glasses (ref. 42). $<n>$ is defined as $<n> = \Sigma f_i$, where $f_i$ and $n_i$ are, respectively, the atomic fraction and the coordination number of the $i$th constituent, and $n_\text{BO} = 4 - \Sigma z_i/\Sigma f_i$, where $M_i$ and $z_i$ are respectively the atomic fraction (after deduction of the number of charge compensators) and the valence of the $i$th modifying cation, and $f_i$ is the fraction of the $j$th glass-forming cation. b, The temperature dependence of $\nu$ for different glass-forming systems. The vertical bar marks the glass transition temperature $T_g$ above which sharp rises are observed, particularly for fragile supercooled liquids\(^{(43)}\). Figure reproduced with permission from ref. 42, © 2007 Wiley.
can be negative, leading to unusual or extreme behaviour as well as coupling between stretch and shear or bend and twist. Carbon nanotube sheets\(^2\), for example, exhibit in-plane auxeticity. By contrast, cork has an anisotropic cellular structure (Fig. 2d). If tensile stress is applied normal to the radial growth, \(\nu \leq 0\) in the direction of growth and \(\nu > 0\) orthogonal to this\(^6\). By alternating entrant and re-entrant honeycomb layers, Grima et al. have shown how structures with \(\nu = 0\) can be generated in particular directions, leading to cylindrical shaped curvatures\(^6\).

Directional auxetic properties were originally envisaged by Saint-Venant\(^8\) for anisotropic materials and later by Lempriere\(^9\) for composites. In inorganic materials, anisotropic auxetic behaviour was suggested for iron pyrites with \(\nu = 1/7\) in some directions. Arsenic, antimony and bismuth are highly anisotropic in single-crystal form and their calculated Poisson’s ratios are negative in some directions. In \(\alpha\)-cristobalite, Poisson’s ratios range from +0.08 to –0.5, depending on direction (Fig. 2c)\(^23\), with an aggregate expected to be negative\(^25\). Many cubic metals when stretched in the [110] direction become auxetic\(^14\). Likewise, many zeolites show off-axis swings in \(\nu\) on rotation\(^11\). Influenced by the presence of extra-framework water and also templating molecules, recent calculations predict oscillations in \(\nu\) of 0.5 to –0.5 for 45° rotations\(^23\). Such anisotropic auxetic behaviour might well influence adsorption chemistry, if crystals are stressed along specific directions\(^23,33\).

Broadly speaking, extreme Poisson’s ratios in single crystals are found to be strongly correlated with elastic anisotropy\(^13\). For example, in \(\text{Ag}_2[\text{Co(CN)}_4]\) the metals form an alternate layered structure containing auxetic motifs (Fig. 2c) which expands along the \(c\) axis but contracts in the basal plane under isotropic compression\(^7\): that is, the compressibility \(\kappa\) has different signs in different crystallographic directions. This behaviour is also expected to be associated with anisotropic Grüneisen parameters, whereby negative linear compressibility in specific directions should be accompanied by negative thermal expansion, which is also observed\(^26\) and is huge compared with related compounds like \(\text{H}_2[\text{Co(CN)}_4]\), \(\text{ZrW}_2\text{O}_8\) or \(\text{Cd(CN)}_6\) (ref. 77).

**Poisson’s ratio during phase transformations**

At different temperatures and pressures, crystalline materials can undergo phase transitions\(^3\) and, attracting considerable debate, so too can glasses and liquids\(^34,35,39-41\). Whenever a phase boundary is crossed or criticality is approached, the isothermal compressibility
\( \kappa_f \) rises anomalously. In fluids this derives from the reorganization of density fluctuations and in crystals from reconfiguration of nanodomains. Accordingly, \( B/G \rightarrow 0 \) and therefore Poisson's ratio decreases. Figure 5a illustrates this for a volume transition in a polymer gel close to a critical point\(^{82} \) and Fig. 5b for the \( \alpha-\beta \) transition in crystalline quartz\(^{34,36} \). Similar behaviour is reported for different gel concentrations\(^{35} \) and for different quartz grain sizes\(^{34} \), both of which affect the phase transition temperatures. In all cases the transitions are of first order, and accompanied by a very narrow minimum in \( \nu \), mirroring the behaviour of the isothermal bulk modulus \( B \). These substantial negative swings in \( \nu \) provide a distinctive universal signature for phase transitions, whatever the type of material. In mixed valence transitions in \( \text{YbInCu}_3 \) (ref. 61), the cubic crystal structure does not change; but the bulk modulus softens and Poisson's ratio drops over a narrow range of temperature near 67 K. Softening of the bulk modulus also occurs for the ferroelastic cubic–tetragonal transition in \( \text{BaTiO}_3 \) in the vicinity of the Curie point, with an auxetic minimum in \( \nu \) (ref. 86).

Negative elastic moduli, for which Poisson's ratio falls outside the range \(-1 \) to \( \frac{1}{2} \), entail instability (Fig. 1b) which in some cases can be constrained. For transformations governed by stress-induced diffusion, the compressibility is predicted to diverge\(^{25} \), the bulk modulus softening to zero corresponding to a substantial lowering of \( \nu \). But this is a slow process for which the relaxation time increases as the critical temperature is approached. For anisotropic single crystals such as \( \text{KH}_2\text{PO}_4 \), the shear elastic tensor element \( C_{\text{66}} \) softens to zero during phase transformation\(^1 \). Softening of the shear or the bulk modulus of perovskite minerals\(^{11} \) has been reported, and martensitic transformations are also characterized by a change in shear elastic moduli associated with changes in crystal structure. Poisson's ratios are typically not reported in such studies; in anisotropic solids they depend on multiple tensor elements. For the glass-to-rubber transition in polymers the shear modulus may change by more than a factor of a thousand, and the bulk modulus by about a factor of two\(^{14} \). As illustrated in Fig. 2c, \( \nu \) is about 0.3 in the glassy regime rising to nearly 0.5 in the rubbery regime\(^{26} \). Inorganic glasses exhibit similar behaviour above the glass transition \( T_g \). The occurrence of flow indicates that the shear modulus tends to zero and Poisson's ratio to 0.5, as can be clearly seen for fragile melts in Fig. 4b.

### Shock-wave melting of metals

Despite its importance across the physical sciences, melting remains incompletely understood in terms of temperature–pressure melting curves and the underlying equations of state\(^{26} \). Nevertheless, significant experimental advances have been made in high-pressure/high-temperature physics where Poisson's ratio offers a unifying approach\(^{13,32,83,88} \). Figure 5c compiles data from the shock-wave melting of metals. The inner and outer pressure limits of the Earth's core surround the melting of Fe, underlining the relevance of these experiments for determining the temperature of the core by parameterizing the equations of state\(^{88} \). Melting metals at these extreme temperatures and pressures is clearly also relevant in developing new materials capable of withstanding extreme conditions.

Shock melting is accompanied by a sharp increase in Poisson's ratio to the liquid value of 0.5, pinpointed by the intersection of the shock adiabatic, or Hugoniott, with the melting curve obtained from the equations of state\(^{35} \). Despite the adiabatic nature, most of the melting thresholds are initiated by the small dip in \( \nu \) expected for first-order transitions. Melting is traditionally understood to occur as the average root-mean-square displacement of atoms in the solid state approaches \( \sim \)10% of the average interatomic separation—the so-called Lindemann criterion\(^{26} \). More specifically, melting coincides with the momentary rise in \( \kappa \), the onset of intersite diffusion and \( G \rightarrow 0 \). All these related components, both before melting and on melting, contribute to the striking melting signature in Poisson's ratio (Fig. 5c).

Another interesting observation from Fig. 5c is the same crystalline metallic phase generally persisting up to \( T_m \). For molybdenum, though, melting is anticipated by an intermediate phase transition near 150 GPa. Originally interpreted as a bcc to hcp transition\(^8 \), recent X-ray measurements of the melting curve for Mo, made in a diamond-anvil cell, suggest that values of Poisson's ratio before \( T_m \) which are unusually high for bcc metals (Fig. 1c), point to a new intermediate non-crystalline phase\(^{26} \)—perhaps a low-density polyamorph. Also included in Fig. 5c are the brittle–ductile \( \nu \) thresholds taken from Fig. 7c. Mo for example melting from the plastic region, with Fe on the borderline.

### Polyamorphic phases in tetrahedral glasses

Polyamorphism occurs when amorphous phases in the same liquid or supercooled state share the same composition, but differ in density and entropy\(^7,99 \). The HDA phase generally has higher entropy than the LDA phase\(^9 \), in which case the slope of the phase boundary \( dT/dP = dV/dS < 0 \). Polyamorphism is not in dispute, but whether or not transformations between polyamorphic phases are of first order is controversial\(^{38,54,59,79,80,90} \). In addition to LDA and HDA amorphous ice\(^{38,59} \), polyamorphism has been reported in many tetrahedral glasses\(^9 \). For silica under pressure Si–O polyhedral change from tetrahedral coordination eventually to octahedral coordination\(^{31} \) reminiscent of the high-density SiO\(_2\) crystalline phase stishovite. For both HDA ice\(^{38} \) and densified silica\(^{9} \), careful in situ sound velocity experiments reveal major changes in elastic moduli at these phase transformations. Values of Poisson's ratio are shown in Fig. 5d for silica\(^9 \). Starting from low values of \( \nu \) indicative of an LDA phase, densification results in a significant rise in \( \nu \) as the HDA phase is formed, but this is preceded by a downward dip, indicative of a first-order transition. Decompression returns a densified tetrahedral phase\(^{38} \).

Since these discoveries, a wealth of new densified HDA phases obtained from crystalline precursors have been reported\(^9,92 \). Creating LDA phases by this route initially proved more challenging, as decompression without cavitation is difficult to achieve in condensed matter. An alternative approach has been discovered that involves the amorphization of microporous crystalline materials, such as zeolites\(^{38,91,95} \), tungstates\(^{96} \) or metal–organic frameworks\(^9 \). Notwithstanding the considerable directional swings exhibited by single crystals\(^{23,24} \), Poisson's ratio for these low-density crystalline materials typically averages out around 0.2. Amorphization occurs at pressures of a few gigapascals\(^{91,96} \) at ambient temperature and close to \( T_m \) at ambient pressure\(^{97} \). In situ small-angle X-ray scattering
Low-frequency collective modes and the boson peak

The driving force for polymorphic transitions in microporous zeolites seems to lie in the strong phonon band found at low frequencies at the start of the vibrational density of states (VDOS), preceded by a narrow band related to the rotation of connected tetrahedra (Fig. 8a and Box 2)\(^{44}\). In glasses this feature in the VDOS is generally referred to as the boson peak (because it generally scales with the Bose–Einstein function), and its origin has been fiercely argued over for the past two decades\(^ {29}\). During microporous collapse, however, a strong correlation exists between the intensity and frequency of terahertz vibrations and the material density \(\rho\) (ref. 94) which can be attributed to librationally driven resonances of zeolitic subunits and which decrease as the HDA glass is formed (Fig. 8a). This densification behaviour of the low-frequency VDOS is reflected more generally across the whole of the glassy state\(^ {29,108}\), the frequency \(\omega_{\text{BP}}\) increasing and the size \(A_{\text{BP}}\) decreasing with increasing \(\rho\). Densified silica provides a good example\(^ {41}\). Indeed, a universal curve can usually be obtained by normalizing to \(\omega_{\text{BP}}\) and \(A_{\text{BP}}\).

There is a lot of experimental evidence that the boson peak in the glassy state has transverse character, with a suspicion that its frequency \(\omega_{\text{BP}}\) may be linked to the Ioffe–Regel limit, where the mean free path of phonons approaches their wavelength and beyond which they no longer propagate\(^ {29,110-103}\). Strong confirmation for this view has come from the simulations shown in Fig. 8b which replicate experimental findings. Moreover, \(\omega_{\text{BP}}\) equates with the
Exciting frequency $\omega_{IR}^{T}$ at the Ioffe–Regel limit for transverse waves, compared with the exciting frequency for longitudinal waves $\omega_{IR}^{L}$, which far exceeds $\omega_{IR}^{T}$. In a similar way, $A_{BP}$ scales with the VDOS for transverse phonons as the structure is densified. As $A_{BP}$ decreases, $\nu$ should increase with decreasing $G$ (Box 2) and, beyond the plastic limit, plastic flow should occur (Fig. 6). Conversely, if the collective dynamics of connected polyhedra are significant, $\nu$ will be reduced with increased $G$ encouraging embrittlement beyond the

Figure 8 | Boson peak and melt fragility. a, Reduction in low-frequency collective terahertz band during the collapse of zeolite Y with densification \(^{94}\) (left) ending in the formation of a glass. Zeolite subunits a and B cages and double six-fold rings (D6R) features are retained in the LDA phase, even when 90% of the zeolite has amorphized. Reproduced with permission from ref. 94, © 2005 AAAS. Micrographs of zeolite and final glass (right) reveal onset of viscous flow as part of the LDL–HDL transition. Reproduced from ref. 93, © 2003 NPG. b, Reduction in the size of the boson peak ABP = $D(\omega)/\omega$ calculated for a 2D glass-forming system under increasing pressure $P$, where $D(\omega)$ is the VDOS for acoustic modes \(^{103}\). c, Temperature dependence of the viscosity $\eta$ versus $T_g/T$ of the HDL and LDL supercooled phases together with the HDA and LDA glasses associated with the collapse of zeolite A. This shows how the increase in melt fragility $m$ follows the LDA–HDA increase in densification \(^{93}\). The classical strong liquid SiO\(_2\), whose fragility falls between those of the two liquid phases, is included for comparison. d, Temperature dependence ($T_g/T$) of the structural relaxation time $\tau$ calculated for the 2D glass in b, showing the increase in melt fragility with increasing pressure $P$ (ref. 103). Note that the fragility is given by $m = [\log(\eta(T)/(\eta_T/T))]_{T_g}$ and that $\eta$ and $\tau$ are related by $\eta = G_\infty\tau_\alpha$ (Box 2). elast limit\textsuperscript{31,32}. Indeed, Poisson’s ratio provides a sharp criterion for differentiating brittleness from ductility in crystalline\textsuperscript{33,34} and in amorphous\textsuperscript{35,36} metals (see Fig. 7c). A more controversial relationship is between $\nu$ and the fragility $m$ of the corresponding supercooled liquid\textsuperscript{96–101,104} (Fig. 7a). Together with the degree of non-ergodicity $f_0$, frozen into the glass \textsuperscript{79,101,106}, the melt fragility $m$ is measured at the glass transition $T_g$ (Box 2) where the viscous relaxation time reaches $\approx 100$ s and the liquid is considered solid\textsuperscript{79,101,107–109}. Its elastic properties, however, clearly differ from those measured under ambient conditions (Fig. 4b). How, then, can the dynamics of the liquid state be related to the elastic properties of the solid state? Indeed, how do solids melt?

**Melt fragility and solid elastic properties**

**Melt fragility** The hugely different viscous properties of liquids are illustrated in the familiar Angell plot of log $\eta$ versus $T_g/T$, where $\eta$ is shear viscosity, shown in Box 2 (ref. 108). In particular, liquid fragility is defined by the steepness of shear viscosity $\eta$ as a function of reciprocal temperature as $T_g$ is approached\textsuperscript{30,102–109}, differentiating ‘strong’ liquids such as silica from ‘fragile’ liquids like molecular melts. The structural relaxation time $\tau$ of the liquid is directly related to $\eta$, so strong melts rheologically approach $T_g$ much more gradually than fragile melts (Box 2). This distinction is even greater at the melting temperature $T_m$ where solid and liquid coexist but where liquid structural relaxation times can differ by as much as $10^6$. Accordingly solids—crystals or glasses—form strong liquids melt or soften far more slowly than those forming fragile liquids: that is, these transformations are much more viscoelastic (Fig. 2c), as can be seen, for example, in $\nu$ versus $T/T_g$ curves (Fig. 4b) by the very different rates at which Poisson’s ratio approaches 0.5 when glasses soften.

With densification, supercooled liquids become more fragile. The increase in fragility can be seen in Fig. 8c for the LDA–HDA transitions underpinning the collapse of a low-density zeolite\textsuperscript{97}; the viscosity of the corresponding fragile HDL liquid meets the glass transition $T_g$, from above far more steeply than the viscosity of the LDA phase from below $T_g.$ Atomistic simulations for a 2D glass-forming system\textsuperscript{110} reveal similar behaviour, with $m$ increasing with increasing pressure (Fig. 8d). Comparing densification changes in $m$ (Fig. 8c and 8d) with the magnitude of the terahertz peak in the glassy state (Fig. 8a and 8b), it is clear that these are inversely related. Strong liquids form glasses with many more collective modes than do fragile liquids. Strong liquids, too, are good glass formers, whereas fragile liquids are prone to crystallize. Glass formation and crystallization are competitive kinetic processes, with collective modes favouring the former.

**Poisson’s ratio and non-ergodicity** Covering a broad range of single-phase glasses, two interesting empirical relationships have emerged linking melt fragility with the elastic properties of the glass\textsuperscript{100–102,105,106}: $m$ versus $B/G$ and $m$ versus $\alpha$. The ratio $B/G$ relates directly to Poisson’s ratio $\nu$ and $\alpha$ to the non-ergodicity factor $f_0$ (ref. 79; Box 2), which describes the extent of the departure from thermodynamic equilibrium. The plot of $m$ versus $B/G$ (Fig. 7a) reveals how Poisson’s ratio $\nu$ increases across many glasses, as the melts from which they are quenched increase in fragility $m$ (refs 100–102). Although objections to this relationship were originally voiced\textsuperscript{104,110}, many of these have been overcome as more glasses have been added\textsuperscript{97,101,102,106,111,112} and the central proposition that “the fragility of a liquid (might be) embedded in the properties of its glass”\textsuperscript{110} has generally been strengthened. Although it is true that the point scatter in the $m$ versus $B/G$ plots is considerable, it is also clear that groups of glasses can be differentiated\textsuperscript{97,111}, forming an approximately radial arrangement from modified oxide glasses through single glass formers to the dense metallic glasses. The overall distribution narrows towards the glasses associated with the strongest liquids\textsuperscript{79,79}. Although silica is usually considered the strongest of these, experiments on zeolite amorphisation reveal that for new low-density liquids (LDL) $m \leq 10$ (ref. 93; Fig. 8c), with the associated LDA glasses being topologically ordered\textsuperscript{79,99,104}. The $m$ versus $\alpha$ plot\textsuperscript{103,106} (Fig. 7b) shows that when liquid fragility $m$ increases, glasses become more ergodic, with $f_0$ (Box 2) decreasing. Specifically, $f_0$ equates with the autocorrelation function of the liquid density fluctuations over the longest timescales\textsuperscript{79,101,106}. It is readily obtained from inelastic X-ray scattering experiments at different temperatures\textsuperscript{113}, measuring the extent to which density fluctuations in the melt are captured in the structure of the glass\textsuperscript{40,105,109}.

From the empirical relationships $m$ versus $B/G$ and $m$ versus $\alpha$ it is clear that $\nu$ and $\alpha$ must also be interrelated across families of glasses, meaning that the least ergodic glasses (small $\alpha$) are the most distortable (small $\nu$) and vice versa. This important conclusion can be better understood by recognizing that the non-ergodicity of a glass is related to the ratio of the sound velocities $V_V/V_L$ (ref. 100), which in turn records the density fluctuations in the glass (Box 2). These ripples in the nanostructure are considered to be related in turn to the size of the boson peak $A_{BP}$ (refs 100,101,109). If $\alpha \propto B/G$, then glasses with the strongest boson peak should have the largest non-ergodicity ($f_0$ at $T_g$) and therefore the smallest $\alpha$. As $\alpha$ correlates with $m$ (refs 105,106), their associated melt fragilities will also be the lowest (Fig. 7b), as will their Poisson’s ratio (Fig. 7a), their shear resistance and, beyond the yield point, their tendency to crack (Fig. 7c): strong liquids form brittle glasses slowly, fragile liquids ductile glasses rapidly.

The original relationship\textsuperscript{110} between $m$ and $\alpha$ has recently been systematically developed to account for the presence of secondary relaxation processes\textsuperscript{306}. These are particularly prevalent in polymers and their associated liquids which are very fragile. Figure 7b shows the correlation extending over more than twice the previous range\textsuperscript{110}, further strengthening the evidence that the correlation between melt fragility and vibrational properties of the corresponding amorphous solid is a universal feature of glass formation.

**Brittle–ductile transformation**

Ductility and brittleness relate to the extreme response of materials strained outside their elastic limits, so any relationship with $\nu$ would seem at first non-intuitive. However, Poisson’s ratio measures the resistance of a material to volume change ($B$) balanced against the resistance to shape change ($G$). Occurring within the elastic regime, any links with properties beyond the yield point must necessarily involve the time-dependent processes of densification and/or flow, already discussed for glasses above. Just as viscoelastic behaviour is expressed in terms of time-dependent bulk and shear moduli, with Poisson’s ratio $\nu(t)$ gradually changing between elastic values, we might expect the starting value of $\nu$ to provide a metric for anticipating mechanical changes, not just in glasses but also in crystalline materials, resulting in ductility (starting from a high $\nu$) or embrittlement (starting from a low $\nu$). At either extreme the microstructure will play a part, whether through cracks, dislocations, shear bands, impurities, inclusions or other means\textsuperscript{114}.

**Polycrystalline materials**

Polycrystalline materials, in the idealized case where there is no preferred orientation, are macroscopically isotropic. Unlike glasses which are generally homogeneous and isotropic but lack atomic long-range order\textsuperscript{79,101,106}, polycrystalline materials have unit cell symmetry but atomic periodicity is broken internally by dislocations and impurities, and externally by grain boundaries\textsuperscript{40,31}. Although there is no simple link between interatomic potentials and mechanical toughness in polycrystalline materials, Poisson’s ratio $\nu$ has proved valuable for many years as a criterion for the brittle–ductile transition exhibited by metals\textsuperscript{40,31,211,115}, just as it is now helping to distinguish brittle glasses from ductile glasses (Fig. 7c) which, from Fig. 7a, are associated with strong and fragile melts respectively\textsuperscript{79,100,101}. DOI: 10.1038/NMAT3134
The old proposal that grains in polycrystalline materials might be cemented together by a thin layer of amorphous material “analogous to the condition of a greatly undercooled liquid” has often been challenged. However, recent atomistic simulations of crystalline grains and grain boundaries seem to confirm the dynamic consequences of this idea in many details. The driving force for this is the large entropy of the glassy state, which, upon crystallization, is released through the formation of grain boundaries. These boundaries act as nucleation sites for the growth of new crystalline phases.

**Metallic glasses** Because direct experimental evidence is lacking, linking melt fragility and mechanical toughness for polycrystalline metals can only be speculative. In metallic glasses, though—particularly in bulk metallic glasses (BMGs) that are cast by slow cooling like conventional glasses—sufficient data on elastic moduli and toughness are available, as well as on melt fragility, to test these ideas quantitatively. In the first place, the threshold between brittleness and ductility in metallic glasses is very abrupt (Fig. 7c). From the most brittle metallic glasses to the toughest, fracture energies $E_{\text{fracture}}$ increase by as much as four decades. The brittle–ductile threshold occurs close to $B/G \approx 2.4$ ($\nu = 0.32$), and is generally higher than the thresholds reported for polycrystalline metals. Plastic flow is also more sharply defined than for crystalline metals. Plastic flow in metallic glasses occurs very locally in shear bands, compared with polycrystalline metals where flow is dislocation-mediated, and delocalized by associated work-hardening.

Turning now to the BMG melt fragilities, $m$ rises with $B/G$, but not as steeply as for network and molecular liquids and their glasses. The index, which is directly relevant to modern materials. Auxetic behaviour is an obvious example, as is the distinctive signature of Poisson’s ratio for phase transitions, including melting. Conversely, the dynamics of the liquid state are contributing to our understanding of the elastic properties of the glassy state via Poisson’s ratio and, in turn, the distinction between the brittleness and ductility of materials. For the future, the numerical metric that Poisson’s ratio provides will be advantageous in researching and developing new materials, marrying the mechanical response of diverse components, from the nanoscale to the macroscale through variable changes in shape and volume.

**Future perspectives** Scientists from many different fields still ignore the variability of Poisson’s ratio. In finite-element simulation for instance, calculations in the elastic or ductile regimes usually assumes that $\nu$ is fixed and ~0.3. In physics, $\nu$ is often assumed to have little effect on the vibrational density of states, although it shows up explicitly in the Debye equation. Therefore, we hope that this Review on Poisson’s ratio will encourage researchers and engineers to pay more attention to this index, which is directly relevant to modern materials. Auxetic behaviour is an obvious example, as is the distinctive signature of Poisson’s ratio for phase transitions, including melting. Conversely, the dynamics of the liquid state are contributing to our understanding of the elastic properties of the glassy state via Poisson’s ratio and, in turn, the distinction between the brittleness and ductility of materials. For the future, the numerical metric that Poisson’s ratio provides will be advantageous in researching and developing new materials, marrying the mechanical response of diverse components, from the nanoscale to the macroscale through variable changes in shape and volume.
